

Deep Learning for NLP Summary

Daniel Saggau

2/4/2021

Motivation word embeddings

Deep Learning models understand numerical representations Texts are sequences of symbolic units Step 1 in any NLP deep learning model: Turn symbols (e.g., words) into vectors

word embeddings are dense (= sparse), trainable word vectors Allows us to calculate similarities between words, e.g., with cosine similarity:

Word embeddings can be trained from scratch on supervised data: Initialize W randomly Use as input layer to some model (CNN, RNN, ...) During training, back-propagate gradients from the model into the embedding layer, and update W Result: Words that play similar roles in the training task get similar embeddings For example: If our training task is sentiment analysis, we might expect (awesome, great) ~ 1

Supervised training sets tend to be small (labeled data is expensive) Many words that are relevant at test time will be infrequent or unseen at training time The embeddings of infrequent words may have low quality, unseen words have no embeddings at all. We have more unlabeled than labeled data. So let's pretrain embeddings on the unlabeled data first.

Word2Vec

Mikolov et al. (2013): Efficient estimation of word representations in vector space.

distributional hypothesis: "a word is characterized by the company it keeps"

- Skipgram

The skipgram task is to maximize the likelihood of the context words, given their center word: Expressed as a negative log likelihood loss:

- CBOW Task

The continuous bag of words (CBOW) task is to maximize the likelihood of the center words, given their context words: Expressed as a negative log likelihood loss:

- Naive softmax model

- Hierarchical softmax model
- Negative sampling model

Instead of predicting a probability distribution over whole vocabulary, predict binary probabilities for a small number of word pairs. This is not a language model anymore. but since we only care about the word vectors, and not the skip gram/CBOW predictions, that's not really a problem.

- FastText

Even if we train Word2Vec on a very large corpus, we will still encounter unknown words at test time

Extension of Word2Vec by **Bojanowski et al. (2017)**: Enriching Word Vectors with Subword Information.

Design choice: Fine-tune embeddings on task or freeze them?

- Pro fine-tuning: Can learn/strengthen features that are important for the task
- Pro freezing: We might overfit on training set and mess up the relationships between seen and unseen words
- Both options are popular

Applications of pre-trained word embeddings

CNN

An architecture is an abstract design for a neural network

Examples of architectures: * Fully Connected Neural Networks * Convolutional Neural Networks (CNNs) * Recurrent Neural Networks (RNNs) * Transformers (self-attention)

The choice of architecture is often informed by assumptions about the data, based on our domain knowledge

translation invariance: The features that make up a meaningful object do not depend on that object's absolute position in the input.

sequentiality: NLP: Sentences should be processed left-to-right or right-to-left. This one is falling out of fashion, since people are replacing recurrent neural networks with self-attention networks.

Are these assumptions true?

Of course not. But they are a good way of thinking about why certain architectures are popular for certain problems. Also, for limiting the search space when deciding on an architecture for a given project.

Convolutional layers

Technique from Computer Vision (esp. object recognition), by LeCun et al., 1998 Adapted for NLP (e.g., Kalchbrenner et al., 2014) Filter banks with trainable filters So what is a filter? What is a filter bank?

1-D convolution

Let's say that we want to train a linear regression model to predict some variable of interest from each datapoint. Since the raw data is noisy, it makes sense to smoothe it with our rolling average filter first: $y = wh + b$; $h = (f \times x)_{jjjj}$ But maybe we should weight the datapoints in our 7-day window differently? Maybe we should give a higher weight to datapoints close to the current day j ? We can manually engineer a filter that we think is better, for example: # TODO Alternative: Let the model choose the optimal filter parameters, based on the training data. How? Gradient descent!

Bias and nonlinearities: * In a real CNN, we usually add a trainable scalar bias b , and we apply a nonlinearity g (such as the rectified linear unit): K #TODO Edge cases: * Possible strategies for when the filter overlaps with the edges (beginning/end) of x : * Outputs where filter overlaps with edge are undefined, i.e., h has fewer dimensions than x ($K - 1$ fewer, to be exact) * Pad x with zeros before applying the filter * Pad x with some other relevant value, such as the overall average, the first/last value, ... Stride: * The stride of a convolutional layer is the "step size" with which the filter is moved over the input * We apply f to the j 'th window of x only if j is divisible by the stride. * In NLP, the stride is usually 1.

Convolution with more than one axis

Extending the convolution operation to tensors with more than one axis is straightforward. Let $X \in \mathbb{R}^{J_1 \times \dots \times J_L}$ be a tensor that has L axes and let $F \in \mathbb{R}^{K_1 \times \dots \times K_L}$ be a filter. * The dimensionalities of the filter axes are called filter sizes or kernel sizes ("kernel width", "kernel height", etc.) * From now on, we assume that the filter is applied to a symmetric window around position j , not just to positions to the left of j . (The rolling average was a special scenario, #TODO are not available on day j .) Then the output $H = F \times X$ is a tensor with L axes, where

Channels

So far, we have assumed that each position in the input (each day or each pixel) contains a single scalar. Now, we assume that our input has M features ("channels") per position, i.e., there is an additional feature axis: $X \in \mathbb{R}^{J_1 \times \dots \times J_L \times M}$ Example: * $M = 3$ channels per pixel in an RGB (red/green/blue) image * In NLP: dimensionality of pretrained word embeddings Then our filter gets an additional feature axis, which has the same dimensionality as the feature axis of X :

TODO

During convolution, we simply sum over this new axis as well

TODO

Filter banks

A filter bank is a tensor that consists of N filters, which each have the same shape. The filters of a filter bank are applied to X independently, and their outputs are stacked (they form a new axis in the output). So let this be our input and filter bank:

Then our output is a tensor of shape $H \in \mathbb{R}^{J \times L \times N}$ (assuming that we are padding the first L axes of X to preserve their dimensionality in H) where:

Assumptions behind convolution Translation invariance: Same object in different positions. * Parameter sharing: Filters are shared between all positions. Locality: Meaningful objects form coherent areas * In a single convolutional layer, information can travel no further than a few positions (depending on filter size) Hierarchy of features from simple to complex: * In computer vision, we often apply many convolutional layers one after another * With every layer, the information travels further, and the feature vectors become more complex * Pixels \rightarrow edges \rightarrow shapes \rightarrow small objects \rightarrow bigger objects

Pooling layers

Pooling layers are parameter-less Divide axes of H (excluding the filter/feature axis) into a coarse-grained “grid”. Aggregate each grid cell with some operator, such as the average or maximum. Example (shown without a feature axis): When pooling, we lose fine-grained information about exact positions In return, pooling allows us to aggregate features from a local neighborhood into a single feature. * For example, if we have a neighborhood where many “dog features” were detected (meaning, shapes that look like parts of a dog), we want to aggregate that information into a single “dog neuron”

In computer vision, we often apply pooling between convolutional layers. Repeated pooling has the effect of reducing tensor sizes.

CNNs in NLP

Images are 2D, but text is a 1D sequence (of words, n-grams, etc). Words are usually represented by M -dimensional word embeddings (e.g., from Word2Vec) So on text, we do 1-D convolution with M input features: * Input matrix: $X \in \mathbb{R}^{J \times M}$ * Filter bank of N filters: $F \in \mathbb{R}^{K \times M}$; $K < J$ * Output matrix: $H \in \mathbb{R}^{J \times N}$ * (assuming that we padded X with zeros along its first axis) Usually, CNNs in NLP are not as deep as CNNs in Computer Vision – often just one convolutional layer.

Pooling is less frequently used in NLP. If the task is a word-level task (i.e., we need one output vector per word), we can simply use the output of the final convolutional layer – no pooling needed. If the task is some sentence-level task (i.e., we need a single vector to represent the entire sentence), we usually do a “global” pooling step over the entire sentence after the last convolutional layer:

RNN

Assumption: Text is written sequentially, so our model should read it sequentially “RNN”: class of Neural Network architectures that process text sequentially (left-to-right or right-to-left) Generally speaking:

- Internal “state” h
- RNN consumes one input $x(j)$ per time step j
- Update function: $h(j) = f(x(j), h(j-1); \theta)$
- where parameters θ are shared across all time steps

Vanilla RNN

#TODO

Backpropagation through time RNNs are trained via “backpropagation through time” To understand how this works, imagine the RNN as a Feed-Forward Net (FFN), whose depth is equal to the sentence length For now, let’s pretend that every time step (every layer) has its own (j) dummy parameters θ , which are identical copies of theta

LSTM

Two states:

- h (“short-term memory”)
- c is (“long-term memory”)

Candidate state \tilde{h} in Rd corresponds to h in the Vanilla RNN d Interactions are mediated by “gates” in $(0, 1)$, which apply elementwise: * Forget gate f decides what information from c should be forgotten Input gate i decides what information from \tilde{h} should be added to c * Output gate o decides what information from c should be exposed to h Each gate and the candidate state have their own parameters

Gated Recurrent Unit

Proposed by *Cho et al. (2014)* Lightweight alternative to LSTM, with only one state and three sets of parameters State h is a dynamic “interpolation” of long and short term memory Reset gate r in $(0, 1)^d$ controls what information passes from h to candidate state \tilde{h}

Bidirectional RNNs

The bidirectional RNN yields two sequences of hidden states: #TODO Question: If we are dealing with a sentence classification task, which states should we use to represent the sentence? #TODO * Concatenate $[h_{\rightarrow}; h_{\leftarrow}]$, because they have “seen” the entire sentence #TODO For tagging task, represent the j ’th word as $[h_{\rightarrow}; h_{\leftarrow}]$ Question: Can we use a bidirectional RNN for autoregressive language modeling? * No. In autoregressive language modeling, future inputs must be unknown to the model (since we want to learn to predict them). * We could train two separate autoregressive RNNs (one per direction), but we

cannot combine their hidden states before making a prediction In sequence-to-sequence (e.g., Machine Translation), the encoder can be bidirectional, but the decoder cannot (same reason)

Limitations of RNNs

At a given point in time j , the information about all past inputs is “crammed” into the state h (and c for an LSTM) So for long sequences, the state becomes a bottleneck For Machine Translation, this means that the source sentence is read exactly once, condensed into a single vector, and then the target sentence is produced. Question: Is this how you would translate a sentence?

- A human translator might look at the source sentence multiple times, and translate it “bit by bit”
- Attention is meant to mimick this process Proposed by Bahdanau et al. 2015, developed into stand-alone architecture (“Transformer”) by Vaswani et al. 2017 Currently the most popular architecture for NLP This week: Attention as a way to make RNNs better Next week: Transformers

Attention

The basic recipe

- One query vector
- J key vectors:
- J value vectors:
- Scoring function

Maps a query-key pair to a scalar (“score”) a may be parametrized by parameters θ

Step 1: Apply a to q and all keys k_j to get scores (one per key):

Step 2: Turn e into probability distribution with the softmax function

Step 3: α -weighted sum over V yields one R_{dv} -dimensional output vector o

TODO

Transformers

- Cross attention and self attention
- Parallelized attention
- Multi-layer attention
- Masked self-attention
- Residual connections and layer normalization
- The Transformer architecture
- Position encodings

Hyperparameter Optimization

Transfer Learning

What is Transfer Learning?

Wikipedia says: "Transfer learning is a research problem in machine learning that focuses on storing knowledge gained while solving one problem and applying it to a different but related problem."

How it works with word2vec

Train word2vec on some "fake task" (DBOW or Skip-gram) Extract the stored knowledge (a.k.a. embedding) or: Directly download embeddings from the web Perform a different (supervised) task using the embeddings

Challenges: If no embedding for a word exists, it cannot be represented. Workaround:

- Train subword (character n-gram) embeddings
- Represent OOV word as combination of them

This is already a special case of Tokenization

Tokenization examples:

- Whitespace tokenization
- N-grams
- Character n-grams
- Characters

Fine-grained tokenization

Difficulties:

- When using embeddings (or other models/methods) for transferring knowledge, one has to stick to this method's tokenization scheme.
- Using words as tokens leads to vocabulary sizes of easily $> 100k$, which is undesirable.
- Characters as tokens lead to a very small vocabulary size but aggravate capturing meaning.
- Using (sets of) n-grams is kind of heuristic.

Smart alternatives:

- BytePair encoding
- WordPiece
- SentencePiece

BytePair encoding (BPE)

Data compression algorithm Gage (1994)

Considering data on a byte-level Looking at pairs of bytes:

- 1 Count the occurrences of all byte pairs
- 2 Find the most frequent byte pair
- 3 Replace it with an unused byte

Repeat this process until no further compression is possible **Open-vocabulary neural machine translation Sennrich et al. (2016)** Translation as an open-vocabulary problem Word-level NMT models:

- Handling out-of-vocabulary word by using back-off dictionaries
- Unable to translate or generate previously unseen words
- Subword-level models alleviate this problem

Adapt BPE for word segmentation Sennrich et al. (2016) Goal: Represent an open vocabulary by a vocabulary of fixed size → Use variable-length character sequences Looking at pairs of characters:

1. Initialize the the vocabulary with all characters plus end-of-word token
2. Count occurrences and find the most frequent character pair, e.g. "A" and "B" (triangle! Word boundaries are not crossed)
3. Replace it with the new token "AB"

Only one hyperparameter: Vocabulary size (Initial vocabulary + Specified no. of merge operations) *Repeat this process until given $|V|$ is reached*

WordPiece

Voice Search for Japanese and Korean Schuster & Nakajima (2012)

Specific Problems:

- Asian languages have larger basic character inventories compared to Western languages
- Concept of spaces between words does (partly) not exist
- Many different pronunciations for each character

WordPieceModel: Data-dependent + do not produce OOVs

1 Initialize the the vocabulary with basic Unicode characters (22k for Japanese, 11k for Korean) #TODO Spaces are indicated by an underscore attached before (of after) the respective basic unit or word (increases initial $|V|$ by up to factor 4) 2 Build a language model using this vocabulary 3 Merge word units that increase the likelihood on the training data the most, when added to the model Two possible stopping criteria: Vocabulary size or incremental increase of the likelihood

BERT

Alternatives to BERT

Limitations // Shortcomings of BERT Pretrain-finetune discrepancy BERT artificially introduces [MASK] tokens during pre-training [MASK]-token does not occur during fine-tuning → Lacks the ability to model joint probabilities → Assumes independence of predicted tokens (given the context) Maximum sequence length Based on the encoder part of the Transformer → Computational complexity of Self-Attention mechanism scales quadratically with the sequence length BERT can only consume sequences of length smaller or equal 512

XLNet Yang et al., 2019 Autoregressive (AR) language modeling vs. Autoencoding (AE)

- AR: Factorizes likelihood to $p(x) = \prod_{t=1}^T p(x_t | x_{<t})$
- Only uni-directional (backward factorization instead would also be possible)
- AE: Objective to reconstruct masked tokens x from corrupted sequence \hat{x} : $p(x | \hat{x}) = \prod_{t=1}^T m_t \cdot p(x_t | \hat{x})$, m_t as masking indicator

Drawbacks / Advantages

- No corruption of input sequences when using AR approach
- AE approach induces independence assumption between corrupted tokens
- AR approach only conditions on left side context
 - No bidirectionality

Alternative objective funktion

Permutation language modeling (PLM) Solves the pretrain-finetune discrepancy Allows for bidirectionality while keeping AR objective Consists of two "streams" of the Attention mechanism * Content-stream attention * Query-stream attention Manipulating the factorization order Consider permutations z of the index sequence $[1, 2, \dots, T]$ → Used to permute the factorization order, not the sequence order. Original sequence order is retained by using positional encodings PLM objective (with ZT as set of all possible permutations):

Content- vs. Query-stream

Content-stream

"Normal" Self-Attention (despite with special attention masks) → Attentions masks depend on the factorization order Info about the position in the sequence is lost, see Sets of queries (Q), keys (K) and values (V) from content stream* Yields a content embedding denoted as $h\theta(xz \text{ smaller or equal } t)$

Query-stream

Access to context through content-stream, but no access to the content of the current position (only location information) Q from the query stream, K and V from the content stream* Yields a query embedding denoted as $g\theta(xz < t, zt)$

Additional encodings: Relative segment encodings: * BERT adds absolute segment embeddings ($EA \& EB$) * XLNet uses relative encodings ($s + \& s -$) Relative Positional encodings: * BERT encodes information about the absolute position ($E0, E1, E2, \dots$) * XLNet uses relative encodings ($Ri-j$)

- Partial Prediction: Only predict the last tokens in a factorization order (reduces optimization difficulty)
- Segment recurrence mechanism: Allow for learning extended contexts in Transformer-based architectures, see
- No independence assumption:

T5

- A complete encoder-decoder Transformer architecture
- All tasks reformulated as text-to-text tasks
- From BERT-size up to 11 Billion parameters
- Effort to measure the effect of quality, characteristics & size of the pre-training resources
- Common Crawl as basis, careful cleaning and filtering for English language
- Orders of magnitude larger (750GB) compared to commonly used corpora

Performed experiments with respect to architecture, size & objective .. details of the Denoising objective .. fine-tuning methods & multi-tasks learning strategies Conclusions Encoder-decoder architecture works best in this "text-to-text" setting More data, larger models & ensembling all boost the performance * Larger models trained for fewer steps better than smaller models on more data * Ensembling: Using same base pre-trained models worse than complete separate model ensembles Different denoising objectives work similarly well Updating all model parameters during fine-tuning works best (but expensive)

ELECTRA

(Small) generator model G + (large) Discriminator model D Generator task: Masked language modeling Discriminator task: Replaced token detection ELECTRA learns from all of the tokens (not just from a small portion, like e.g. BERT)

Joint pre-training (but not in a GAN-fashion): G and D are (Transformer) encoders which are trained jointly G replaces [MASK]s in an input sequence * Passes corrupted input sequence $x_{corrupt}$ to D Generation of samples: with approx. 15% of the tokens masked out (via choice of k) D predicts whether $x_t, t \in 1, \dots, T$ is "real" or generated by G

- Softmax output layer for G (probability distr. over all words)
- Sigmoid output layer for D (Binary classification real vs. generated)

Using the masked & corrupted input sequences, the (joint) loss can be written down as follows: Loss functions: Combined:

with λ set to 50, since the discriminator's loss is typically much lower than the generator's.

Generator size: Same size of G and D: * Twice as much compute per training step + too challenging for D Smaller Generators are preferable ($1/4 - 1/2$ the size of D)

Weight sharing (experimental): Same size of G and D: All weights can be tied G smaller than D: Share token & positional embeddings

Note: Different batch sizes (2k vs. 8k) for ELECTRA vs. RoBERTa/XLNet explain why same number of steps lead to approx. $1/4$ of the compute for ELECTRA.

Model distillation

Model compression scheme: Motivation comes from having computationally expensive, cumbersome ensemble models. Bucila et al. (2006) Compressing the knowledge of the ensemble into a single model has the benefit of easier deployment and better generalization Reasoning: * Cumbersome model generalizes well, because it is the average of an ensemble. * Small model trained to generalize in the same way typically better than small model trained "the normal way". Distillation: Temperature T in the softmax: #TODO Knowledge transfer via soft targets with high T from original model. When true labels are known: Weighted average of two different objective functions

DistilBERT Sanh et al. (2019)

Student architecture (DistilBERT): * Half the number of layers compared to BERT Half of the size of BERT, but retains 95% of the performance * Initialize from BERT (taking one out of two hidden layers) * Same pre-training data as BERT (Wiki + BooksCorpus)

Training and performance Distillation loss $L_{ce} = \sum_i p_i \cdot \log(s_i) + \text{MLM-Loss}$ $L_{mlm} + \text{Cosine-Embedding-Loss}$ L_{cos} Drops NSP, use dynamic masking, train with large batches * Rationale for "only" reducing the number of layers: Larger influence on the computation efficiency compared to e.g. hidden size dimension

The $O(n^2)$ problem

Quadratic time & memory complexity of Self-Attention Inductive bias of Transformer models: Connect all tokens in a sequence to each other * Pro: Can (theoretically) learn contexts of arbitrary length * Con: Bad scalability limiting (feasible) context size

Resulting Problems: Several tasks require models to consume longer sequences Efficiency: Are there more efficient modifications which achieve similar or even better performance?

Efficient Transformers Tay et al. (2020)

Broad overview on so-called "X-formers":

Efficient & fast Transformer-based models * Reduce complexity from $O(n^2)$ to (up to) $O(n)$ * Claim on-par (or even) superior performance Different techniques used: * Fixed/Factorized/Random Patterns * Learnable Patterns (extension of the above) *

Low-Rank approximations or Kernels * Recurrence (see e.g. Transformer-XL (Dai et al., 2019)) * Memory modules

Side note: Most Benchmark data sets not explicitly designed for evaluating long-range abilities of the models. Recently proposed #todo

Introducing Patterns

Reasoning:

Making every token attend to every other token might be unnecessary Introduce sparsity in the commonly dense attention matrix

Example:

#ToDo

Self Attention

Reasoning: Most information in the Self-Attention mechanism can be recovered from the first few, largest singular values Introduce additional k-dimensional projection before self-attention

DeBERTa

Disentangled Attention: Each token represented by two vectors for content (H_i) and relative position ($P_i|j$) Calculation of the Attention Score:

#todo

with content-to-content, content-to-position, position-to-content and position-to-position attention

Disentangled Attention Standard (Single-head) Self-Attention:

#todo

GPT Models

Transformer Training: Masked language modeling (MLM) BERT learns an enormous amount of knowledge about language and the world through MLM training on large corpora. Application: finetune on a particular task Great performance! What's not to like? (In what follows I will use BERT as a representative for this class of language models and only talk about BERT – but the discussion includes RoBERTa, Albert, XLNet etc.)

Problems with BERT

- You need a different model for each task. (Because BERT is differently finetuned for each task.)

- Not realistic in many real deployment scenarios, e.g., on mobile devices.
- Human learning: we arguably have a single model that solves all tasks!
- Question: Is there a framework that allows us to create a single model that solves all tasks?
- BERT has two training modes, first (MLM) pretraining, then finetuning.
- Finetuning is supervised learning, i.e., learning from labeled examples.
- Arguably, learning from labeled examples is untypical for human learning.
- You never learn a task solely by being presented a bunch of examples, without explanation.
- Instead, in human learning, there is almost always a task description.
- Example: How to boil an egg. “Place eggs in the bottom of a saucepan.
- Fill the pan with cold water. Etc.” (Notice that this is not an example.)
- Question: Is there a framework that allows us to leverage task descriptions?
- BERT has great performance, but it only has great performance if the training set is fairly large, generally 1000s of examples.
- This is completely different from human learning!
- We do use examples in learning, but in most cases, only a few.
- Example: Maybe the person teaching you how to boil an egg will show you how to do it one or two times.
- But probably not 10 times Definitely not a 1000 times
- More practical concern: it’s very expensive to label 1000s of examples for each task (there are many many tasks).

Question: Is there a framework that allows us to learn from just a small number of examples? This is called **few-shot learning**. More subtle aspect of the same problem (i.e., large training sets): **overfitting** Even though performance looks good on standard train/dev/test splits, the deviation between the training set and the data actually encountered in real application can be large. So our benchmarks often overestimate what performance would be in reality. *There is always a shift in reality. A model trained for 2020 wont be able to adapt to changes in 2021. This is the finetuning. Great idea in priciple but not generalizable/external validity*

GPT: Intro

Like BERT, GPT is a language model. But not MLM, but a conventional language model: it predicts the next word (or subword). (*this rose smells good example*) Like BERT, GPT is trained on a huge corpus, actually an even huger corpus. (much larger) Like BERT, GPT is a transformer architecture. * Difference 1: GPT is a **single model** that aims to solve all

tasks. * It can also switch back and forth between tasks and solve tasks within tasks, another human capability that is important in practice. “fluidity” * Difference 2: GPT leverages task descriptions. * Difference 3: GPT is effective at few-shot learning.

In-context learning which technically is not deep learning.

GPT: Two types of learning

Does in-context learning (similar problems) Models sees examples.

GPT: Effective in-context learning

zeroshot, oneshot, fewshot when zeroshot, the accuracy is very low. It can leverage a single training example a huge amount. By adding more, it gets better. The big jump is the first. With enough labeled examples, you don't need a task description. With one shot, there is a huge millage due to task descriptions.

X-shot comparison and effect of larger corpora

few shot is performing best but only marginal difference with huge corpora.

Fine-tuning (not used by GPT)

Zero-shot (no gradient update)

The model predicts the answer given only a natural language description of the task. No gradient update.

#TODO one shot:

Few-shot (no gradient update) Gets several examples. No gradient update performed.

Architecture: Effect of size on model. Getting better, the more parameters are given.

Compute PeaFLOP/s-days

Looks linear, the more compute the use, the better your complexity. The larger model, even better. The main concern is that there is not enough text.

GPT3 results on tasks

Impression of types of tasks used in NLP to test capability of models.

Lambda task

GPT3 we have context and the model is asked to predict the next word (or several). It does not change its parameters. It is just doing the language change objective. Designed to make it hard to predict the next word.

SuperGLUE BoolQ CB (true/false/neither) COPA RTE (similar to natural language inference) WiC WSC MultiRC (true/false) ReCoRD

Context given to gpt3: * Three “training” articles to condition gpt3 * Title and subtitle of a 4th article gpt3 then has to generated the body of the 4th article Evaluation: Humans are

presented the human-generated original article and the gpt3-generated article and are asked to identify which is fake.

Summary

The average person has difficulty distinguishing human-generated and gpt3-generated news. However, the non-average person probably can distinguish them quite well. There's also evidence that machines are able to distinguish human-generated and gpt3-generated news. This has great significance for preventing abuse of AI technology.

GPT limitations

Next generation

- Repetitions
- Lack of coherence
- Contradictions

Common sense physics E.g., “If I put cheese in the fridge, will it melt?” See below

Comparison tasks GPT3 performs poorly when two inputs have to be compared with each other or when rereading the first input might help. E.g., is the meaning of a word the same in two sentences (WiC). E.g., natural language inference, e.g., ANLI Not a good match for left-to-right processing model. Possible future direction: bidirectional models

Self-supervised prediction on text All predictions are weighted equally, but some words are more informative than others. Text does not capture the physical world. Many tasks are about satisfying a goal – prediction is not a good paradigm for that.

Low sample efficiency Humans experience much less text than GPT3, but perform better. We need approaches that are as sample-efficient as humans, i.e., need much less text for same performance.

Size/Interpretability/Calibration Difficult to use in practice due to its size. Behavior hard to interpret Probability badly calibrated

Discussion: Does GPT3 “learn” from context? GPT3 learns a lot in pretraining. But does it really learn anything from task description and the few-shot prefix? Notice that no parameters are changed during fewshot “learning”, so it is not true learning. If you give the same task again to GPT3 an hour later, it has retained no information about the previous instance. How much of human learning is “de novo”, how much just uses existing scales.

Three OpenAI papers GPT (2018): Improving language understanding by generative pre-training GPT2 (2019): Language Models are Unsupervised Multitask Learners GPT3 (2020): Language Models are Few-Shot Learners We're not interested here in the (small) differences between these papers and will focus on GPT3, but refer to it as GPT. Recommendation: Read GPT3 paper

Marcus & Davis (1)

(biological reasoning) You poured yourself a glass of cranberry juice, but then you absent-mindedly poured about a teaspoon of grape juice into it. It looks okay. You try sniffing it, but you have a bad cold, so you can't smell anything. You are very thirsty. So GPT continues: you drink it. You are now dead. (physical reasoning)

- You are having a small dinner party. You want to serve dinner in the living room. The dining room table is wider than the doorway, so to get it into the living room, you will have to
- GPT continues: remove the door. You have a table saw, so you cut the door in half and remove the top half. (social reasoning)
- You are a defense lawyer and you have to go to court today. Getting dressed in the morning, you discover that your suit pants are badly stained.
- However, your bathing suit is clean and very stylish. In fact, it's expensive French couture; it was a birthday present from Isabel.
- You decide that you should wear GPT continues: the bathing suit to court.
- You arrive at the courthouse and are met by a bailiff who escorts you to the courtroom.(object and individual tracking)
- Yesterday I dropped my clothes off at the dry cleaner's and I have yet to pick them up. Where are my clothes?
- GPT continues: I have a lot of clothes.(psychological reasoning)
- Janet and Penny went to the store to get presents for Jack.
- Janet said, "I will buy Jack a top." "Don't get Jack a top," says Penny. "He has a top.
- He will GPT continues: get a top." "I will get Jack a top," said Janet. (non sequiturs)
- At the party, I poured myself a glass of lemonade, but it turned out to be too sour, so I added a little sugar.
- I didn't see a spoon handy, so I stirred it with a cigarette.
- But that turned out to be a bad idea because GPT continues: it kept falling on the floor.
- That's when he decided to start the Cremation Association of North America, which has become a major cremation provider with 145 locations.

GPT: Discussion

GPT: Ethical considerations

In general, a machine does not know (and probably does not care) what consequences its words will have in the real world. * Example: advice to someone expressing suicidal thoughts Text contains bias, language models learn that bias and will act on it when deployed in the real world. * Discrimination against certain job applicants * A future much better version of GPT could be used by bad actors: spam, political manipulation, harassment (e.g., on social media), academic fraud etc. A future much better version of GPT could make a lot of jobs redundant: journalism, marketing etc. One partial solution: legal requirement to disclose automatic generation ("Kennzeichnungspflicht")

GPT authors on APTs (advanced persistent threats, e.g., North Korea) . . . language models may not be worth investing significant resources in because there has been no convincing

demonstration that current language models are significantly better than current methods for generating text, and because methods for “targeting” or “controlling” the content of language models are still at a very early stage.

Experiment: make GPT3 generate text in “male” and “female” contexts and find generated words more correlated with one vs the other. Male contexts: “He was very . . .”, “He would be described as . . .” Female contexts: “She was very . . .”, “She would be described as

Experiment (analogous to gender): make GPT3 generate text in racial contexts and find generated words more correlated with one vs the other. Contexts: “The RACE man was very . . .”, “The RACE woman was very . . .”, “People would describe the RACE person as . . .” etc.

Bias: What to do? Debias the biased model (huge literature on this) Control training text (very hard to do in practice) GPT3 authors: not really a problem NLP people can address, need interdisciplinary approach

Response to green concerns about GPT3

You only have to train the model once. If you then use it a lot, that can be efficient. Generating 100 pages of text with GPT3 costs a few cents in energy – perhaps ok? Distill the model once it is trained (e.g., Distilbert)
